Abstract

In methanolic extracts of the biomass from agitated cultures of *Aronia arbutifolia* and *Aronia* × *prunifolia* grown on four variants of the Murashige and Skoog (MS) medium, with different concentrations of plant growth regulators (PGRs): BA and NAA (0.5–3.0 mg/l), the quantities of phenolic acids (19 compounds) and flavonoids (11 compounds) were estimated using the LC-DAD method. The amounts of individual metabolites and total contents were dependent on the concentration of PGRs in MS medium variant. The maximum total amounts of phenolic acids and flavonoids reached 360.80 and 65.26 mg/100 g DW, and 659.51 and 78.34 mg/100 g DW for *A. arbutifolia* and *A. × prunifolia*, respectively. The main metabolites in the biomass of both plants were chlorogenic acid, rosmarinic acid and quercitrin (max. 175.94, 147.98 and 41.14 mg/100 g DW, and 260.34, 225.26 and 78.34 mg/100 g DW, respectively). The cells of both plants convert the exogenously supplied hydroquinone into its β-D-glucoside—arbutin. The maximal total content of the product accumulated in the biomass and media reached 83.55 and 73.62 mg/g DW. The obtained results demonstrated for the first time a high biosynthetic potential of agitated cultures of both plants.

LC-DAD	Liquid chromatography with photodiode array detection
MS	Murashige and Skoog
NAA	1-Naphthaleneacetic acid
PGR	Plant growth regulator

Introduction

The groups of plant metabolites that are important in therapy, in the production of healthy food and also in cosmetology include polyphenolic compounds, such as phenolic acids and flavonoids (Hussain et al. 2012). These two groups of compounds have been proven to have valuable antioxidant properties (Krolicka et al. 2008; Procházková et al. 2011; Giri et al. 2012). Rich natural sources of these compounds are still being sought. An interesting proposition is to use, for example, biotechnological solutions by attempting to obtain antioxidants from plant cultures in vitro (Matkowski 2008).

In recent years, many phenolic acids, both derivatives of cinnamic acid and of benzoic acid, and also depsides have been proven to have progressively more biological properties of vital importance in therapy, e.g. immunostimulatory, anti-aggregative and anti-cancer (Thurrow 2012; Piazzon et al. 2012; Meng et al. 2013; Kakkar and Bais 2014; Döring and Petersen 2014). Flavonoid compounds, despite anti-inflammatory, antiproliferative and vasoprotective activities, have recently been demonstrated to have neuroprotective and anti-HIV properties and to be valuable in the treatment of

periprosthetic osteolysis and the prevention of obesity (Arts and Hollman 2005; Pasetto et al. 2014; D'Andrea 2015).

The genus *Aronia* includes North American species which have been successfully grown in Asia and Europe (Kulling and Rawel 2008). The most well-known and studied species is *Aronia melanocarpa* (black chokeberry). Information on the chemical composition of *A. arbutifolia* (red chokeberry) and *A. × prunifolia* (purple chokeberry)—a hybrid of *A. arbutifolia* and *A. melanocarpa*, is modest. Analysis of the fruit extracts has shown them to contain flavonoids and hydroxycinnamic acids, among others (Taheri et al. 2013). Our recent phytochemical studies of extracts from the fruits and leaves collected in two different growing seasons from soil-grown plants, from which cultures were derived in vitro, have demonstrated, among other things, the high amounts of two depsides—chlorogenic acid and neochlorogenic acid (found both in the fruits and leaves), and of selected flavonoid compounds—quercetin, quercitrin and rutoside, and also rosmarinic acid (found in the leaves) (Szopa et al. 2017).

In our previous studies with stationary shoot cultures of *A. arbutifolia* and *A. × prunifolia*, we had proven their ability to accumulate both phenolic acids and flavonoids in notable amounts (Szopa et al. 2018). Encouraged by those results, we had decided to establish agitated cultures of both plants, as a type of cultures more valuable for practical applications, and as a preliminary step for growing cultures in large-scale installations.

The agitated shoot cultures were maintained on four variants of the Murashige and Skoog (MS) medium (Murashige and Skoog 1962), which contained different amounts of plant growth regulators (PGRs): cytokinin (BA) and auxin (NAA), in a concentration range of 0.5 to 3.0 mg/l. Methanolic extracts from the biomass were analyzed with the LC-DAD method for phenolic acids—cinnamic and benzoic acid derivatives (19 compounds), and cinnamic acid as a precursor of one subgroup of phenolic acids, and flavonoid aglycones (4 compounds) and glycosides (7 compounds).

The agitated cultures grown on the MS medium containing 2 mg/l BA and 2 mg/l NAA were also used to investigate the ability of the cells of shoots cultured in vitro to perform biotransformation of exogenously delivered hydroquinone into arbutin—its β -D-glucoside. Arbutin, a phenolic glycoside, occupies an important position in medicine, as a compound effective in the treatment of urinary tract inflammation, and in cosmetology, as a valuable and safe skin bleaching agent. More recent studies have additionally proven the antitussive, antifungal and antioxidant properties of arbutin (Ekiert et al. 2013b; Migas and Krauze-Baranowska 2015).

In our present study the aim was to optimize the process of biotransformation of hydroquinone into arbutin. This consisted in testing different doses of the precursor—hydroquinone (100–400 mg/l), and different ways of administering it

(undivided single dose and divided into 2 and 3 portions). Methanolic extracts from the biomass and lyophilizates of the media were analyzed by LC-DAD to determine the amounts of the product—arbutin.

The choice of the composition of the culture medium was dictated by the desire to compare the biosynthetic potential of the cells in these cultures with the results of earlier studies of agitated cultures of *A. melanocarpa*. The optimization of the biotransformation of hydroquinone into arbutin in *A. melanocarpa* cultures was performed with agitated microshoots cultivated on the variant of the MS medium containing 2 mg/l each of BA and NAA (Kwiecień et al. 2013).

The entire study, of both the ability of cells from the agitated cultures of *A. arbutifolia* and *A. × prunifolia* to accumulate endogenously phenolic acids and flavonoids, and of an efficient biotransformation of an exogenous precursor—hydroquinone, was aimed at exploring the biosynthetic potential of cells from agitated cultures of the two plants. To date, no research centre has carried out similar studies with agitated cultures of either *A. arbutifolia* or *A. × prunifolia*. Previous biotechnological studies of the two plants by other centres concerned only the development of micropropagation protocols (Brand and Cullina 1992).

Materials and methods

Basal shoot in vitro cultures

The shoot in vitro cultures of *Aronia arbutifolia* (L.) Pers. and *Aronia × prunifolia* (Marsh.) Rhed. were initiated as described previously (Szopa et al. 2018). The shoot cultures were maintained on the MS (Murashige and Skoog 1962) medium supplemented with 1.0 mg/l BA (6-benzylaminopurine) and 1.0 mg/l NAA (1-naphthaleneacetic acid). The MS medium contained 3% sucrose (w/v) and was solidified with 0.8% agar (w/v) (Duchefa Biochemie, Netherlands). The cultures were grown in vessels for plant tissue cultures (100 ml, 66 mm × 59 mm), with special Magenta B-caps (Sigma-Aldrich, USA), in a phytotron at 25 ± 2 °C under constant artificial light ($16 \mu\text{mol} \times \text{m}^{-2} \times \text{s}^{-1}$) and were transferred onto the same fresh medium every 4 weeks.

Endogenic accumulation of metabolites

Experimental in vitro cultures

In order to perform the experiment, the basal cultures of *A. arbutifolia* and *A. × prunifolia* (as described above) were used to establish agitated shoot cultures in 300 ml Erlenmeyer flasks. The inoculum consisted of 2 g of fresh shoots for one flask containing 100 ml of MS liquid medium with 3% sucrose (w/v) (pH 5.7). Four variants of the MS medium

with different concentrations of BA and NAA: 0.5 mg/l BA and 2 mg/l NAA; 2 mg/l BA and 2 mg/l NAA; 2 mg/l BA and 1 mg/l NAA; 3 mg/l BA and 1 mg/l NAA were tested. The shoots were cultured on a rotary shaker (Altel, Poland) at 140 rpm, with a vibration amplitude of 35 mm, in the same physical culture conditions as described above. The agitated cultures were maintained for 28 days (4 weeks), in three replications, 10 flasks per replication ($n = 10$), for each MS medium variant.

Extraction and LC-DAD analysis

The extraction was carried out as follows: 1 g of each dried (by lyophilization) and powdered (in a mortar) biomass was subjected (twice) to extraction with 50 ml of boiling analytical grade methanol for 2 h under a reflux condenser. The combined extracts (100 ml) were concentrated to dryness, and the residues were dissolved in 2 ml of HPLC grade methanol (Merck, Germany). Respective experimental media were collected (40 ml) and lyophilized, and then dissolved in methanol (5 ml). The qualitative and quantitative LC-DAD analyses were performed using Merck-Hitachi apparatus (autosampler L 2200, pump L 2130, column oven L 2350, diode array detector (DAD) L 2455) in a UV range of 200–400 nm (detection wavelength was set at 254 nm), and a Purospher® RP-18e column (Merck, 250 × 4 mm, 5 μ m) thermostated at 25 °C. Gradient elution was applied acc. to Ellnain-Wojtaszek and Zgorka (1999); Sułkowska-Ziaja et al. (2017), the mobile phase was composed of methanol-0.5% acetic acid (1:4, v/v) and methanol. The flow rate was 1 ml/min, injection volume

was 10 μ l. Quantification of the compounds was based on calibration curves by comparing the mean peak areas with those for standard concentrations. Reference standards of phenolic acids—benzoic acid derivatives: 3,4-dihydroxyphenylacetic, gallic, gentisic, p-hydroxybenzoic, protocatechuic, salicylic, syringic, vanillic acids; cinnamic acid derivatives: caffeic, o-coumaric, m-coumaric, p-coumaric, ferulic, hydrocaffeic, isoferulic, sinapic acids, and also a precursor of this group—cinnamic acid; and depsides: chlorogenic, neochlorogenic and rosmarinic acids (Sigma-Aldrich, USA). Reference compounds of flavonoids—aglycones: kaempferol, luteolin, quercetin, myricetin; glycosides: apigenin, cynaroside, hyperoside, quercitrin, rutoside, trifolin and vitexin (Sigma-Aldrich, USA). A representative UV–LC chromatogram is shown in Fig. 1.

Biotransformation of exogenously delivered hydroquinone

Experimental in vitro cultures

In order to perform the biotransformation experiment, the agitated shoot cultures of *A. arbutifolia* and *A. × prunifolia* were cultured in 300 ml Erlenmeyer flasks containing 100 ml of standard MS liquid medium with 2 mg/l BA and 2 mg/l NAA. The inoculum consisted of 4 g of fresh biomass. The cultures were agitated on a rotary shaker (Altel, Poland) at 140 rpm, with a vibration amplitude of 35 mm, in the same physical conditions as described above.

Fig. 1 The representative LC–UV chromatogram ($\lambda = 254$ nm) of a methanol extract of *A. arbutifolia* shoots cultivated on MS medium with 2 mg/l BA and 1 mg/l NAA

Hydroquinone (Merck, Germany) was introduced to the culture media as an aqueous solution (1 or 2 mg/ml) 14 days after inoculation. It was administered into the culture flasks aseptically through a 0.22 µm membrane filter (Merck-Millipore, Germany). Fresh medium (100 ml) was also added to each flask (pH 5.7). The final concentrations of hydroquinone were: 100, 150, 200, 300 and 400 mg/l of medium. Hydroquinone was administered in a single dose or in split doses as two or three portions added at 24 h intervals. Harvesting of the shoot biomass and culture media was carried out 24 h after the last dose of hydroquinone. The biomass was air dried (at 37 °C) and the media were lyophilized. The experimental combinations were run independently in three replications, $n = 10$, for each plant.

In order to calculate the efficiency of the biotransformation, the following formula was used: efficiency = $a/b \times 100\%$, where ‘a’ is the overall amount of arbutin produced per flask (in the biomass and in 200 ml of medium); ‘b’ is the maximum amount of arbutin that can be theoretically obtained from the applied amount of hydroquinone (calculated from the molar masses of the compounds) acc. to Suzuki et al. (1987).

Extraction and LC-DAD analysis

One gram of each dried and powdered (in a mortar) biomass was subjected (twice) to extraction with 50 ml of boiling analytical grade methanol for 4 h under a reflux condenser. The extracts (100 ml) were evaporated to dryness, and the residues were dissolved in 2 ml of HPLC grade methanol (Merck, Germany). The lyophilized media were also dissolved in HPLC grade methanol up to 5 ml.

The extracts were analyzed by the LC-DAD method of Štambergová et al. (1985). For chromatographic estimation, the same HPLC apparatus was used as described above. The applied separation method consisted of a mobile phase of methanol × water (1:9, v/v) at a flow rate of 1 ml/min. Arbutin and hydroquinone were detected at 285 nm (retention times: 3.8 and 5.6 min., respectively). Qualification and quantification were based on comparisons with reference standards (Sigma-Aldrich, USA). The amounts of the compounds were calculated from calibration curves by comparing the mean peak areas with those for standard concentrations. A representative UV–LC chromatogram is shown in Fig. 2.

Statistical analysis

Results are presented as the mean \pm SD of three independent determinations. Statistical significance of the differences was assessed by one-way ANOVA. Duncan’s test was implemented to identify significant differences in the individual and total contents of estimated compounds,

Fig. 2 The representative LC-UV chromatogram ($\lambda = 285$ nm) of a methanol extract of *A. arbutifolia* shoots cultivated in vitro after experiment of biotransformation of hydroquinone into arbutin

total arbutin content and biotransformation efficiency. The differences were statistically significant when $p < 0.05$. The analyses were performed using STATISTICA version 12 PL software package (StatSoft, Poland).

Results

Biomass increments

Aronia arbutifolia cultures

The shoot cultures of *A. arbutifolia* growing on the tested MS medium variants showed from 2.17- to 2.93-fold increases in dry biomass during 4-week growth cycles. The highest biomass growth was confirmed for MS medium containing 0.5 mg/l BA and 2 mg/l NAA (2.93-fold) and 2 mg/l BA and 2 mg/l NAA (2.79-fold). The shoot cultures were characterized by varied morphology depending on the tested MS medium variant. The shoots growing on MS medium with a small amount of cytokinin (0.5 mg/l BA and 2 mg/l NAA) were elongated and less branched. The shoots growing on other tested MS media with higher amounts of BA were well branched but less elongated (Fig. 3).

Aronia × prunifolia cultures

The shoot cultures of *A. × prunifolia* growing on the tested MS medium variants showed from 2.03- to 3.07-fold increases in dry biomass during 4-week growth cycles. The highest biomass growth was confirmed for MS medium containing 2 mg/l BA and 2 mg/l NAA (3.07-fold) and 0.5 mg/l BA and 2 mg/l NAA (3.02-fold). The shoot cultures were characterized by varied morphology depending on the tested MS medium variant. The shoots growing on MS medium with a small amount of cytokinin (0.5 mg/l BA and 2 mg/l NAA) were elongated and poorly branched, and had well-developed leaves. The shoots growing on other tested MS

media with higher amounts of BA grew very close to each other and had small leaves (Fig. 3).

Accumulation of phenolic acids

Aronia arbutifolia cultures

Of the 20 compounds estimated, the extracts from the biomass of *A. arbutifolia* shoots grown on the four tested MS variants were all found to contain the same five phenolic acids; three depsides—chlorogenic acid, neochlorogenic acid and rosmarinic acid, and 3,4-dihydroxyphenylacetic acid and protocatechuic acid (Table 1). The amounts of

the individual compounds varied greatly, depending on the variant of the growing medium, from 1.27 to 2.40-fold. The largest amounts that accumulated in the shoots were those of chlorogenic acid, ranging from 122.83 to 175.94 mg/100 g DW. The maximum amount of this depside was found on the medium containing 2 mg/l BA and 2 mg/l NAA. Another compound that was also accumulated in large amounts in the shoots was rosmarinic acid. Its amounts varied within even wider limits, from 78.57 to 147.98 mg/100 g DW. The highest amount was found on the MS medium containing 2 mg/l BA and 1 mg/l NAA. The confirmed amounts of 3,4-dihydroxyphenylacetic acid were of a different order of magnitude; they did not exceed 58 mg/100 g DW, and increased about 1.27-fold, depending on the variant of MS medium. The maximum content of 57.39 mg/100 g DW was found on the medium containing 2 mg/l each of cytokinin and auxin. Neochlorogenic acid was accumulated in even smaller amounts, from 17.73 to 28.03 mg/100 g DW. The highest content was confirmed on the medium containing 2 mg/l BA and 1 mg/l NAA. The amounts of protocatechuic acid were very low (max. 3.64 mg/100 g DW). The total amounts of phenolic acids obtained from the biomass of shoots were significant. They ranged from 322.21 to 360.80 mg/100 g DW. The maximum content was found on the MS variant containing 2 mg/l BA and 1 mg/l NAA (Table 1). The phenolic acids were not present in the tested media.

Aronia × prunifolia cultures

Of the 20 compounds estimated in the extracts of *A. × prunifolia* shoots grown on the four MS variants tested, the analysis confirmed in all of them the presence of also five phenolic acids, three depsides—chlorogenic acid, neochlorogenic acid and rosmarinic acid, and 3,4-dihydroxyphenylacetic acid and protocatechuic acid (Table 2). Depending on the composition of the culture media, the amounts of the individual compounds increased within the range from 1.48 to 2.64-fold. The main, quantitatively dominant metabolite was chlorogenic acid. Its amounts ranged from 142.97 to

260.34 mg/100 g DW. The maximum content was confirmed on the medium containing 3 mg/l BA and 1 mg/l NAA. Another compound that was accumulated in large quantities in the cultivated biomass was rosmarinic acid (amounts in the range of 97.80–225.71 mg/100 g DW). On two MS variants, the highest maximal amounts of this metabolite were almost identical—225.71 and 225.26 mg/100 g DW (variants containing 2 mg/l BA and 1 mg/l NAA, and 3 mg/l BA and 1 mg/l NAA). 3,4-Dihydroxyphenylacetic acid was accumulated in smaller amounts, not exceeding 100 mg/100 g DW. The content ranged from 66.80 to 98.65 mg/100 g DW. The maximum amount of this acid was confirmed on the medium containing 3 mg/l BA and 1 mg/l NAA. Neochlorogenic acid was accumulated in even smaller amounts (26.84–70.91 mg/100 g DW). The maximum content was found on the MS medium containing 3 mg/l BA and 1 mg/l NAA. Protocatechuic acid was accumulated in very small quantities (max. 5.50 mg/100 g DW).

The total amounts of phenolic acids were high (339.91–659.51 mg/100 g DW). The maximum content was confirmed in extracts from the biomass of shoots grown on the medium containing 3 mg/l BA and 1 mg/l NAA (Table 2). The phenolic acids were not detected in the media samples.

Accumulation of flavonoids

Aronia arbutifolia cultures

Irrespective of the composition of the growing media, the analysis of extracts from *A. arbutifolia* shoots (analyzed for 11 flavonoid compounds) revealed the presence of quercetin (a flavonoid aglycone) and two of its glycoside conjugates—quercitrin and rutoside (Table 3). The quantitatively predominant metabolite was quercitrin. Its amounts on each MS variant were considerable (35.85–41.14 mg/100 g DW). The highest content was found on the MS variants containing 0.5 mg/l BA and 2 mg/l NAA. The estimated amounts of rutoside were several times lower, equal to

Table 2 Phenolic acid contents (mg/100 g DW \pm SD) in shoot extracts from agitated cultures of *A. × prunifolia* cultivated on tested MS medium variants and in the fruit extracts of soil-grown plant (acc. Szopa et al. 2018)

 nd Not detected

5.39–9.08 mg/100 g DW. The amounts of the aglycone (quercetin) did not exceed 19 mg/100 g DW. The total amounts of the flavonoid compounds differed only 1.13-fold, on the individual MS variants. The largest amounts, equal to 65.26 and 61.11 mg/100 g DW, were confirmed on the media containing, respectively, 0.5 mg/l BA and 2 mg/l NAA, and 3 mg/l BA and 1 mg/l NAA (Table 3). The studied flavonoids were not detected in the media samples.

Aronia \times *prunifolia* cultures

In terms of flavonoid compounds, the analyzed extracts from *A. \times prunifolia* shoots were found to have the same qualitative composition regardless of the MS variant. The analysis confirmed the presence of the same three compounds whose presence had been recorded in extracts from the shoots of *A. arbutifolia*—quercetin, quercitrin, and rutoside (Table 4). The main metabolite was quercitrin. Its amounts ranged from about 32 to 48 mg/100 g DW, depending on the composition of the medium. On the medium containing 3 mg/l BA and 1 mg/l NAA, the quercitrin content was markedly higher (the max. content was 47.86 mg/100 g DW) than on the other three MS variants (32.36–36.60 mg/100 g DW). The amounts of rutoside were several times lower than those of quercitrin (10.21–13.44 mg/100 g DW). The confirmed amounts of quercetin changed within a narrow range, from 14.93 to 17.03 mg/100 g DW. The maximum amounts of both rutoside and quercetin were found on the medium supplemented with 3 mg/l BA and 1 mg/l NAA. On the medium of this composition, the total amount of the three flavonoid compounds was also the highest—equal to 78.34 mg/100 g

DW (Table 4). The flavonoids were not present in the tested media.

Biotransformation of hydroquinone into arbutin: effect of optimization

Aronia arbutifolia cultures

In the experiment, there were no adverse effects of the applied doses of hydroquinone on biomass growth increments; the average increases in dry biomass growth fluctuated around threefold during the 17-day growth period (Fig. 4). Only in the case of the highest doses of the precursor added in one portion (300, 400 mg/l) did we notice some inhibition in the growth of the biomass (2.49 and 2.21-fold increments, respectively), and a darkening of the biomass colour.

Cells from *A. arbutifolia* cultures in vitro exhibited the ability to perform bioconversion of hydroquinone into its β -D-glucoside, arbutin. Arbutin was accumulated mainly in the cultivated biomass (max. 92.08–93.43 mg/g DW for 150–300 mg/l dose of hydroquinone divided into three portions).

Higher accumulation of the product in the media was found when the precursor was administered in single doses (Table 5). The total amount of the product (in the biomass and culture media) was clearly dependent on the concentration of the precursor, and fell within the range from 27.78 to 83.55 mg/g DW. The amounts of arbutin in the cultured biomass varied within wide limits, from 20.56 to

Table 4 Flavonoid contents (mg/100 g DW \pm SD) in shoot extracts from agitated cultures of *A. \times prunifolia* cultivated on tested MS medium variants and in the fruit extracts of soil-grown plant (acc. Szopa et al. 2018)

*Sum of content in the biomass and in the medium

Different letters indicate significant differences between means ($n=3$, $p<0.05$) based on Duncan's test

71.00 mg/g DW, and in the media from 15.61 to 65.72 mg/l of medium. In the case of single low doses of hydroquinone (100, 200 mg/l), the total arbutin content increased from 27.78 mg/g DW (100 mg/l) to 45.09 mg/g DW (200 mg/l). With the highest single doses of hydroquinone (300 and 400 mg/l), the arbutin content dropped to 38.87 and 29.28 mg/g DW, respectively.

Splitting the doses of hydroquinone into portions favoured the biotransformation process; 1.09- to 2.85-fold increase in total arbutin content was found in the biomass and medium. The beneficial effect of splitting hydroquinone doses was particularly pronounced at the higher concentrations of the

precursor (300 and 400 mg/l). The addition of a 400 mg/l dose of the precursor divided into three portions resulted in the highest total arbutin content, equal to 83.55 mg/100 g DW.

The efficiency of the process of biotransformation of hydroquinone into arbutin ranged from 13.00 to 74.33%. When hydroquinone was administered in single doses, only at the low concentrations (100 and 150 mg/l) was the efficiency of the process similar (59.74 and 56.31%). With higher undivided (full) doses of hydroquinone, the efficiency of the process decreased very markedly, from 46.12 to 13.00%. Splitting hydroquinone doses into portions markedly increased

the efficiency of the biotransformation, both at the low and high concentrations. The beneficial effect of splitting hydroquinone doses was particularly evident at the higher concentrations (200–400 mg/l). Administering hydroquinone in portions increased the efficiency by as much as fourfold. The highest efficiency of the process was obtained after administering the smallest doses (100–200 mg/l) divided into three portions (74.33–67.37%) (Fig. 4). With the higher doses of hydroquinone (300 and 400 mg/l), despite dividing them into three portions, the efficiency of the process did not exceed 50%.

A. × prunifolia cultures

In the experiment, there were no adverse effects of the applied doses of hydroquinone on biomass growth increments; the average increases in dry biomass growth fluctuated around fivefold during the 17-day growth period (Fig. 4). Moreover, in the case of the addition of larger portions of hydroquinone (300, 400 mg/l), we did not notice any inhibition in the growth of the biomass, only a slight darkening of the biomass colour.

Cells from *A. × prunifolia* shoot cultures also transformed hydroquinone into arbutin. The product was accumulated mainly in the biomass (max. 99.16% for a 300 mg/l dose of hydroquinone divided into three portions) (Table 6). The arbutin content in the media was low; it was about 10% at the lowest concentrations of hydroquinone (100 mg/l) and

decreased (to 0.84 and 3.66%) with increasing amounts of the precursor (300, 400 mg/l). The total amount of the product in the biomass and the media changed depending on the concentration of hydroquinone. The arbutin content in the cultured biomass ranged from 21.45 to 70.85 mg/g DW, and in the media from 3.98 to 40.03 mg/l of medium. Following the administration of single doses of hydroquinone, the arbutin content in the biomass gradually increased, from 23.98 mg/g DW (100 mg/l) to 46.73 mg/g DW (400 mg/l).

The splitting of hydroquinone doses into portions was favourable to the accumulation of arbutin in the biomass. Following the supplementation of the media with hydroquinone in concentrations of 150–400 mg/l, there was an increase, between 1.71 and 3.30-fold, in the total arbutin content in the biomass and medium.

The maximum total arbutin content in the biomass and the medium, equal to 73.62 mg/g DW, was confirmed after the application of the highest tested dose of hydroquinone (400 mg/l) divided into three portions.

The efficiency of the process ranged from 33.37 to 85.73%. When the culture media were supplemented with single, full doses of hydroquinone, the efficiency gradually decreased with increasing concentration of hydroquinone (from 67.94 to 33.37%). Administering the precursor in split doses resulted in an increase of up to two times in the effectiveness of the biotransformation process. The maximum efficiency of the process was found after administering the smallest doses of the precursor (100 and 150 mg/l)

Table 6 Effects of optimization of bioconversion of hydroquinone as the precursor into arbutin in shoot cultures of *A. × prunifolia*

Concentration of precursor (mg/l)	Method of precursor supply	Total arbutin content (mg/g DW \pm SD)*	Arbutin content in biomass		Arbutin content in medium		Biotransformation efficiency (% \pm SD)

*Sum of content in the biomass and in the medium

Different letters indicate significant differences between means (n = 3, p < 0.05) based on Duncan's test

divided into three portions (85.73 and 81.66%, respectively) (Fig. 4). With hydroquinone delivered in higher doses (above 200 mg/l), the maximum efficiency did not exceed 66.50%.

Discussion

In the agitated cultures of both plants, the increases in dry biomass during the 4-week culture cycles on the tested variants of the MS medium were similar, about threefold. These increases were comparable with those in the agitated cultures of *A. melanocarpa* maintained on the same variants of the MS medium (unpublished). In the agitated shoot cultures of *Hypericum perforatum* (cvs. Elixir, Helos and Topas) (Kwiecień et al. 2015, 2018), *Ruta graveolens* (Ekiert and Czygan 2005) and *Schisandra chinensis* (Szopa et al. 2016) maintained by us previously, we had obtained slightly higher (by several times, from four to ninefold) increases in dry biomass.

The estimated phenolic acids were accumulated in the biomass; no compounds were detected in the media. The same phenomenon was observed in agitated cultures of other plant species, e.g., for schisandra lignans in *S. chinensis* (Szopa et al. 2016), and also for furanocoumarins in *R. graveolens* and *R. graveolens* ssp. *divaricata* (Ekiert and Czygan 2005), and for phenolic acids and flavonoids in *H. perforatum* (cvs. Elixir, Helos and Topas) (Kwiecień et al. 2015, 2018).

The qualitative composition of the free phenolic acids estimated in extracts from the biomass cultured in vitro was the same as in the case of extracts from the fruits of soil-grown plants (Table 1). There were, however, marked quantitative differences. In *A. arbutifolia* shoots cultured in vitro, the main accumulated metabolites were chlorogenic acid (122.83–145.44 mg/100 g DW) and rosmarinic acid (78.57–147.98 mg/100 g DW). The maximum amounts of these metabolites were about 9 times (8.94 and 9.11-fold) higher than in the fruit (16.27 and 16.24 mg/100 g DW, respectively). Also, the amounts of 3,4-dihydroxyphenylacetic acid accumulated in vitro were 2.76 times higher than in fruit extracts. These three metabolites (chlorogenic, neochlorogenic and 3,4-dihydroxyphenylacetic acids) have very valuable biological properties, such as antioxidant, anti-inflammatory, immunostimulating, antiaggregatory and anticancer activities (Petersen and Simmonds 2003; Kampa et al. 2004; Thurow 2012; Ekiert et al. 2013a; Döring and Petersen 2014). The obtaining of significant amounts of them in agitated cultures should be regarded as a success. By contrast, the amounts of neochlorogenic acid were about 3.29 times higher in extracts from the fruit in comparison with in vitro cultured biomass (Szopa et al. 2018).

The total amounts of phenolic acids obtained in vitro were 2.21–2.47 times higher than in extracts from *A. arbutifolia* fruits (Szopa et al. 2018).

It is also important to compare the current results with those obtained previously in stationary cultures of *A. arbutifolia*. What draws the attention are the markedly higher amounts of chlorogenic acid, rosmarinic acid and 3,4-dihydroxyphenylacetic acid in agitated cultures, but a slightly lower neochlorogenic acid content. The total amounts of phenolic acids in the agitated cultures were as much as 2.73–5.42 times higher than in the stationary cultures conducted on media of identical composition of PGRs (Szopa et al. 2018).

Also in the case of *A. × prunifolia*, the qualitative composition of the phenolic acids estimated in vitro was identical to that in extracts from the fruits of soil-grown plants (Table 2). The main metabolites in vitro were chlorogenic acid, rosmarinic acid and 3,4-dihydroxyphenylacetic acid (142.97–260.34, 97.80–225.71 and 66.80–98.65 mg/100 g DW, respectively). The dominant compounds in fruit extracts were: chlorogenic acid and neochlorogenic acid (273.45 and 212.56 mg/100 g DW, respectively). The 3,4-dihydroxyphenylacetic acid and rosmarinic acid contents were very low (4.29 and 9.15 mg/100 g DW, respectively) (Szopa et al. 2017).

The maximum amounts of chlorogenic acid in vitro matched the amounts found in extracts from the fruit. The maximum amounts of neochlorogenic acid were about three times lower, but the amounts of rosmarinic acid and 3,4-dihydroxyphenylacetic acid obtained in vitro were several times higher (Table 2). The maximum total amount of phenolic acids obtained in vitro, approx. 660 mg/100 g DW, was only 1.22 times higher than in extracts from the fruit of *A. × prunifolia* (Szopa et al. 2018). A valuable result obtained in vitro was the very high amount of rosmarinic acid (approx. 226 mg/100 g DW). The comparison with the results obtained earlier in stationary cultures indicates that agitated cultures are a particularly rich source of chlorogenic acid and 3,4-dihydroxyphenylacetic acid. In the stationary cultures of *A. × prunifolia*, the presence of the 3,4-dihydroxyphenylacetic acid had not been confirmed at all (Szopa et al. 2018).

The total amounts of phenolic acids obtained in agitated cultures of *Aronias* were higher than in agitated cultures of *H. perforatum* (cvs. Elixir, Helos and Topas), cultured on MS media with the same composition of PGRs (Kwiecień et al. 2015).

The estimated flavonoids, like phenolic acids, were accumulated in the biomass; no compounds were detected in the media. In agitated cultures of *A. arbutifolia*, the analyses demonstrated the presence of three flavonoid compounds: the flavonoid aglycone—quercetin, and two of its glycosides—quercitrin and rutoside. The main metabolite was quercitrin. The maximum total amount of this group of

compounds, equal to 65.26 mg/100 g DW, was about twice as high as in the fruits of soil-grown plants, in which only the presence of quercetin was confirmed (31.83 mg/100 g DW) (Szopa et al. 2018) (Table 3).

Also in agitated cultures of *A. × prunifolia*, the LC-DAD analysis confirmed the presence of the flavonoid aglycone—quercetin, and its two glycosides: quercitrin and rutoside. The quantitatively dominant compound was also quercitrin. The maximum amount of flavonoid compounds was about 1.8 times higher than in the fruit. In fruit extracts, only the presence of quercetin (44.26 mg/100 g DW) was confirmed. It is interesting that the main metabolite in both *Aronia* cultures in vitro was quercitrin—a compound with many valuable biological activities (Camuesco et al. 2004; Wagner et al. 2006) (Table 4).

The study also proved the influence of the different concentrations of PGRs, BA and NAA, on the accumulation of both phenolic acids and flavonoids. The amounts of individual phenolic acids in *A. arbutifolia* cultures increased between 1.12 and 2.40 times. Also, the total content increased up to 1.12-fold depending on the variant of the MS medium. The best ‘production’ medium was the MS variant containing 2 mg/l BA and 1 mg/l NAA. In the case of flavonoids, their individual amounts varied from 1.13 to 3.16-fold, and the total content increased up to 1.13-fold. The maximum flavonoid contents on all the tested MS medium variants were similar, with the highest amounts confirmed on the MS medium containing 0.5 mg/l BA and 2.0 mg/l NAA, and 3.0 mg/l BA and 1.0 mg/l NAA.

In the case of *A. × prunifolia* cultures, the amounts of individual phenolic acids varied from 1.48- to 2.64-fold, and the total content increased up to 1.22-fold. The best ‘production’ medium proved to be the MS variant containing 3 mg/l BA and 1 mg/l NAA. The same variant favoured the accumulation of flavonoids, and could be a ‘universal’ production medium.

The influence of PGRs on the production of secondary metabolites in in vitro cultivated biomass of different plant species had been proven before, e.g. for anthocyanins in *Vitis vinifera* (Qu et al. 2006), alkaloids in *Lycopodiella inundata* (Bienaimé et al. 2015), isoflavones in *Psoralea cordifolia* (Shinde et al. 2009) and phenolic compounds in *Stevia rebaudiana* (Radić et al. 2016).

Based on the results obtained, it is notable that the cytokinin/auxin ratio had an influence on the accumulation of phenolic compounds in the studied *Aronia* cultures in vitro (Tables 3, 4). The predominance of cytokinin was conducive to the endogenous accumulation of phenolic acids and flavonoids (Karuppusamy 2009; Murthy et al. 2014). Some reports have confirmed the stimulating effect of exogenous benzyladenine (BA) supplementation on the production of saponins in *Panax ginseng* hairy root cultures (Murthy et al. 2014) or withanolide A in suspension cultures of *Withania*

somnifera (Nagella and Murthy 2010). The exogenous supplementation with different cytokinin/auxin ratios was studied e.g. in hairy root cultures of *Cichorium intybus* (Bais et al. 2001). The exogenously added PGRs had an effect on biomass growth and coumarin biosynthesis, wherein transformed roots of *C. intybus* treated with increasing auxin-to-cytokinin ratios lost their capacity for coumarin biosynthesis.

In summary, the results of the research on endogenous accumulation of metabolites demonstrated a high biosynthetic potential of the cells of *A. arbutifolia* and *A. × prunifolia* shoots cultured in vitro in agitated systems. Agitated cultures of *A. × prunifolia* proved to be a rich source of both phenolic acids and flavonoids. The resulting total amounts of these two groups of compounds are, respectively, 1.66- and 1.28-fold higher than in *A. arbutifolia* cultures. As a hybrid, *A. × prunifolia* has a greater biosynthetic potential, which we had proven earlier in our phytochemical studies, and have now demonstrated in a biotechnological study (Szopa et al. 2017, 2018). Moreover, the phenomenon of higher secondary metabolite production in polyploid hybrids is a well-known fact (Lavania 2005).

As part of the ongoing research, we have proven the ability of cells of *A. arbutifolia* and *A. × prunifolia* to perform bioconversion of exogenously administered hydroquinone into its β -D-glucoside, arbutin. Glucosylation reactions are typical of cells in plant in vitro cultures (Tabata et al. 1988). In the majority of cases, the efficiency of the biotransformation process depends on the studied in vitro plant species as well as on the applied scheme of administering compounds—single or multiple doses, and time of supplementation (Carew and Bainbridge 1976; Ishihara et al. 2003). There are many reports on successful possibilities of performing the glucosylation process by different plant tissue cultures. They are capable of glucosylating substrates such as simple phenolic compounds, steroids, terpenoids, cardenolides, as well as hydroquinone into its β -D-glucoside—arbutin (Tabata et al. 1988). The problem is the efficiency of the biotransformation run. The average amounts of arbutin obtained by bioconversion of different precursors fluctuate within a wide range, from 0.9 to 7.4 g/100 g DW (Dušková et al. 1999). Only in a few cases that was possible to obtain satisfactory optimization of this process in in vitro cultivated biomass. In *Datura innoxia* suspension cultures, the efficiency of the biotransformation process reached a maximum of 45%, after supplementing the culture with 10 mM of hydroquinone and incubating it for 24 h (Suzuki et al. 1987). In suspension cultures of *Catharanthus roseus* (Inomata et al. 1991) and *Rauwolfia serpentina* (Lutterbach and Stöckigt 1992), a continuous supply of hydroquinone was provided. The maximum yields of arbutin—9.2 g/l (98% process efficiency) and 18 g/l (83% process efficiency), were obtained after exogenously supplying 364 mM and 242 mM of hydroquinone, respectively, 24 h before harvesting the

biomass. The maximum total amounts of the product, in *A. arbutifolia* and *A. × prunifolia* in vitro cultures equal to 8.35 and 7.36 g/100 g DW respectively, are comparable with those that we had obtained by an analogous optimization procedure in in vitro cultures of *A. melanocarpa*, *Hypericum perforatum*, *Ruta graveolens* and *S. chinensis* (max. 8.2, 7.2, 7.8 and 5.08 g/100 g DW, respectively) (Piekoszewska et al. 2010; Kwiecień et al. 2013; Szopa et al. 2018). Almost all of the amounts obtained after the optimization process were higher than those required by the European Pharmacopoeia 9th ed. for *Uvae ursi folium* (7.0 g/100 g DW) (European Directorate for the Quality of Medicines 2017) and are interesting from a practical point of view.

As a whole, the study results demonstrate for the first time the high biosynthetic potential of cells from agitated cultures of both plants. The obtained results are very interesting and demonstrated a high biosynthetic potential of agitated cultures of both plants. We propose agitated cultures of *A. arbutifolia* and *A. × prunifolia* as a rich source of chlorogenic acid, rosmarinic acid and quercitrin.
